(Received 5 January 2010; published 25 June 2010)

Molecular dynamics computer simulations are used to study the aging dynamics of SiO$_2$ (modeled by the BKS model). Starting from fully equilibrated configurations at high temperatures $T_i \in \{2500, 2750, 3000, 3250\}$ K, the system is quenched to lower temperatures $T_f \in \{2500, 2750\}$ K and observed after a waiting time $t_w$. Since the simulation runs are long enough to reach equilibrium at $T_f$, we are able to study the transition from out-of-equilibrium to equilibrium dynamics. We present results for the partial structure factors, time superposition of intermediate waiting times $t_w$, and Berthier and references therein. The temperature at which the crossover between both regimes occurs is at $T_c \approx 3300$ K, corresponding to the critical MCT temperature of BKS silica. Previous studies of the aging dynamics of BKS silica [25–27] were performed in two steps. First, the system was fully equilibrated at a temperature $T_f > T_c$. Then, the system was quenched to a low temperature $T_f < T_c$, followed by the production runs. Wahlen and Rieger [26] analyze time-dependent correlation functions at different waiting times $t_w$ and Berthier [25] and Scala et al. [27] study the generalized fluctuation dissipation relation and the energy landscape [27]. All three studies [25–27] investigate the early stages of the aging dynamics, i.e., the dynamics was explored on time scales that were much smaller than the equilibrium relaxation time $\tau_{eq}$ at the temperature $T_f$.

I. INTRODUCTION

When a glass-forming liquid is quenched from an equilibrium state at a high temperature $T_i$ to a nonequilibrium state at a lower temperature $T_f$, “aging processes” set in. Provided that crystallization plays no role at $T_i$ (e.g., due to very low crystal nucleation rates), the transition to a final (metastable) equilibrium state occurs on a time scale that corresponds to the typical equilibrium relaxation time $\tau_{eq}$ of the (supercooled) liquid at $T_f$. The dynamics of the system depends on the waiting time $t_w$, which is the time elapsed after the temperature quench. If $\tau_{eq}$ exceeds the waiting time $t_w$ then the system is observed in a transient nonequilibrium state which corresponds to a glass for $t_w \ll \tau_{eq}$. During the aging process, i.e., for $t_w < \tau_{eq}$, thermodynamic properties such as volume and energy are changing and time translation invariance does not hold: correlation functions at time $t_w + t$ and the time origin at $t_w$ do depend not only on the time difference $t$ but also on the waiting time $t_w$.

Recently this aging process has been investigated extensively with experiments [1–6], theoretically [7–9] and with computer simulations. For a more complete summary of previous results, we refer the reader to the references [10,11] and references therein. Computer simulation studies most similar to the work presented here are on attractive colloidal systems [12–15], on the Kob-Andersen Lennard-Jones (KALJ) mixture [16–25], and silica (SiO$_2$) [25–28]. In the case of silica the interpretation of the results is less clear than for the KALJ mixture; e.g., different findings [25,27] have been reported on the violation of the fluctuation-dissipation regime during aging [7–9]. Thus, it remains open whether silica, as the prototype of a glass-forming system forming a tetrahedral network structure, exhibits a different aging dynamics than, e.g., the KALJ model, where the structure is similar to that of a closed-packed hard-sphere structure.

Recent simulation studies on amorphous silica [25–39] have widely used the van Beest, Kramer, van Santen (BKS) potential [40] to model the interactions between the atoms. Although it is a simple pair potential, it reproduces various static and dynamic properties of amorphous silica very well. For BKS silica, the self-diffusion constants $D_o(\alpha=\text{Si}, \text{O})$ show two different temperature regimes: At high temperatures, $D_o$ decays according to a power law, as predicted by the mode coupling theory (MCT) of the glass transition (note, however, that also other interpretations have been assigned to this high temperature regime). At low temperature, $D_o$ as well as the shear viscosity $\eta$ exhibit an Arrhenius behavior with an activation energy of the order of $5$ eV, in agreement with experiment (see [30] and references therein). The temperature at which the crossover between both regimes occurs is at $T_c \approx 3300$ K, corresponding to the critical MCT temperature of BKS silica. Previous studies of the aging dynamics of BKS silica [25–27] were performed in two steps. First, the system was fully equilibrated at a temperature $T_f > T_c$. Then, the system was quenched to a low temperature $T_f < T_c$, followed by the production runs. Wahlen and Rieger [26] analyze time-dependent correlation functions at different waiting times $t_w$ and Berthier [25] and Scala et al. [27] study the generalized fluctuation dissipation relation and the energy landscape [27]. All three studies [25–27] investigate the early stages of the aging dynamics, i.e., the dynamics was explored on time scales that were much smaller than the equilibrium relaxation time $\tau_{eq}$ at the temperature $T_f$. 

\textsuperscript{8}kvollmay@bucknell.edu
In this work, we also consider quenches in BKS silica from a high temperature $T_i$ to a low temperature $T_f$. Different from previous simulation studies, we aim at elucidating the full transient dynamics at $T_f$ from the initial state at $t_w=0$ to equilibrium. To this end, temperatures $T_i$ are chosen such that the system can be fully equilibrated on the typical time span of the MD simulation. Note that the considered temperatures $T_i\in\{2500\text{ K}, 2750\text{ K}, 3000\text{ K}, 3250\text{ K}\}$ are below the critical MCT temperatures $T_c$. Thus, we have access to the full aging dynamics in the experimentally relevant Arrhenius temperature regime that we have mentioned above.

The analysis of time-dependent density correlation functions $C_q(t_w, t_w+t)$ (with $q$ the wave number) and the mean-square displacement $\Delta^2(t_w, t_w+t)$ reveal three different regimes of waiting times $t_w$: In the case of $C_q(t_w, t_w+t)$ (and similarly for $\Delta^2(t_w, t_w+t)$) at early $t_w$, a rapid decay to zero is seen, without forming a plateau at intermediate times. Then, for larger values of $t_w$, a plateau is formed. The height of this plateau grows with waiting time and becomes more pronounced, before in the final regime the plateau height is is seen, without forming a plateau at intermediate times. The functional form of the BKS potential was truncated, as was the Ewald term in real space is also differentiable at the interface. A van der Waals term. Thus the potential between particles $i$ to a low temperature $T_f$.

Different from previous simulations and to check for the lack of a temperature drift, we show in Fig. 2 for exemplatory simulation runs the size of the cubic box was fixed to $L=16.920468 \text{ Å}$ which corresponds to a density of $\rho=2.323 \text{ g/cm}^3$, a value that is very close to the one of real silica glass, $\rho=2.2 \text{ g/cm}^3$ [46].

We investigated the aging dynamics for systems, which were quenched from a high temperature $T_i$ to a low temperature $T_f$. To increase the statistics, for each $(T_i, T_f)$ independent simulation runs were performed. To obtain 20 independent configurations we carried out molecular dynamics (MD) simulations using the velocity Verlet algorithm with a time step of 1.6 $\text{ fs}$ at 6000 $\text{ K}$. The temperature was kept constant at 6000 $\text{ K}$ with a stochastic heat bath by replacing the velocities of all particles by new velocities drawn from the corresponding Boltzmann distribution every 150 time steps. Independent configurations were at least 327 ns apart. Each of these configurations undergoes the following sequence of simulation runs (see also Fig. 1). After fully equilibrating the samples at the initial temperatures $T_i=5000 \text{ K}$ (for 16.35 ns) and $T_f=3760 \text{ K}$ (for 32.7 ns), the system was quenched instantaneously to $T_i\in\{2500\text{ K}, 2750\text{ K}, 3000\text{ K}, 3250\text{ K}\}$. To disturb the dynamics minimally, we used a Nosé-Hoover thermostat [47,48] instead of a stochastic heat bath to keep the temperature at $T_f$ constant. A velocity Verlet algorithm was used to integrate the Nosé-Hoover equations of motion (see Appendix) with a time step of 1.02 $\text{ fs}$. After 0.33 ns the Nosé-Hoover thermostat was switched off and the simulation was continued in the NVE (constant number of particles, volume and energy) ensemble for 33 ns using a time step of 1.6 $\text{ fs}$. Whereas previous simulations used instead the NVT (constant number of particles, volume and temperature) ensemble for the whole simulation run, we chose to switch to the NVE ensemble to minimize any influence on the dynamics due to the chosen heat bath algorithm. For the comparison with previous simulations and to check for the lack of a temperature drift, we show in Fig. 2 for exemplary simulation runs the time temperature $T_f$ as a function of time where $E_{\text{kin}}$ is the time averaged kinetic energy with fluctuations as indicated with error bars. We find that even after switching off the heat...
bath [49] there is no temperature drift for $T=3250$ K and $T=3000$ K and for $T=2500$ K and $T=2750$ K there is only a slight temperature drift, which is of the same order as the temperature fluctuations and the drift occurs only for $t \lesssim 0.6$ ns. For all times $t \gtrsim 0.6$ ns and for all investigated temperatures there is no temperature drift and thus the comparison with previous simulations valid.

III. RESULTS

In all following, we investigate how the structure and dynamics of the system depend on the waiting time $t_w$ elapsed after the quench from $T_i$ to $T_f$. We varied the waiting time in the range $0 \leq t_w \leq 23.98$ ns.

A. Partial structure factor

Figure 3 shows for the temperature quench $T_i=5000$ K to $T_f=2500$ K the partial structure factors $S_{\alpha\beta}(q,t_w)$, $t_w$ for the temperature quench from $T_i=5000$ K to $T_f=2500$ K. Indicated with arrows are the wave vectors $q$, which have been used to determine $C_q(t_w,t_w+t)$ as defined in Eq. (3).
Figs. 6–8 results for the first sharp diffraction peak at q=1.7 Å⁻¹. Waiting times for the solid lines are from bottom to top \( t_w=0, 1.63 \times 10^{-3}, 1.63 \times 10^{-2}, 1.63 \times 10^{-1}, 0.33, 0.49, 1.17, 1.96, 8.83, 16.67, \) and 23.98 ns. The order of solid lines are for increasing \( t_w \) black thin, green (gray) thin, black thick, green (gray) thick, black thin, green (gray) thin, etc. Error bars are as indicated exemplary. The thick dashed line corresponds to \( C_q(t_w, t_w + t) = F_q(q, t) \) at 5000 K.

\((T_i, T_f)\) combinations are very similar. Although Fig. 3 shows \( S(t, q) \) for the largest investigated temperature quench, there is only a slight \( t_w \)-dependence for very short waiting times \( t_w \leq 0.33 \text{ ns} \) and almost no \( t_w \)-dependence for \( t_w \geq 0.33 \text{ ns} \).

B. Generalized incoherent intermediate scattering function

In this section, we focus on the time-dependent generalized intermediate incoherent scattering function \([11]\)

\[
C_q(t_w, t_w + t) = \frac{1}{N_a} \left( \sum_{j=1}^{N_a} e^{i q \cdot (r_j(t_w + t) - r_j(t_w))} \right),
\]

which is a measure for the correlations of the positions at time \( t_w \) and at a later time \( (t_w + t) \). We investigated wave vectors of magnitude \( q=1.7, 2.7, 3.4, 4.6, 5.5 \) and 6.6 Å⁻¹, as indicated with arrows in Fig. 3. We show in Fig. 4 and Figs. 6–8 results for the first sharp diffraction peak at \( q=1.7 \text{ Å}^{-1} \). Similar results are found for all other investigated wave vectors. Figure 4 shows \( C_q(t_w, t_w + t) \) for the largest investigated temperature quench from \( T_i=5000 \text{ K} \) to \( T_f=2500 \text{ K} \) for waiting times \( t_w=0–23.98 \text{ ns} \), as listed in the figure caption of Fig. 4. We find that \( C_q(t_w, t_w + t) \) is dependent on \( t_w \) for all but the last three investigated waiting times. For very short times \( t \leq 5 \times 10^{-5} \text{ ns} \) and zero waiting time, \( C_q(t_w=0, t) \) is well approximated by \( C_q \) of the high temperature \( T_i=5000 \text{ K} \) from which the system has been quenched (see dashed line in Fig. 4). Thus, \( C_q(t_w=0, t) \) for very short times is only dependent on \( T_i \), \( q \) and the particle type, but independent of \( T_f \). For times of the order of \( t=10^{-3} \text{ ns} \), \( C_q(t_w, t_w + t) \) is oscillatory due to the small system size. For times \( t \geq 10^{-3} \text{ ns} \), \( C_q \) decays to zero without forming a plateau for small \( t_w \). With increasing \( t_w \) a plateau is formed, which is independent of \( t_w \) for \( t_w \geq 0.33 \text{ ns} \).

To characterize the plateau height we define \( F(t) \) as the time average of \( C_q(t_w, t_w + t) \) for times \( 2.55 \text{ ps} \leq t \leq 6.64 \text{ ps} \). The inset of Fig. 5 shows that for large waiting times \( F(t) \) becomes independent of \( t_w \) and of \( T_f \). To test this independence of \( T_f \), further, we show \( F \) as a function of \( q \) for \( t_w=16.67 \text{ ns} \) in Fig. 5. We find that the plateau height is dependent on the particle type and decreases with decreasing \( q \), but \( F \) is independent of \( T_f \).

The plateau in \( C_q \) becomes more horizontal with decreasing final temperature \( T_f \), as can be seen by the comparison of Fig. 4 (\( T_f=2500 \text{ K} \)) and Fig. 6 (\( T_f=3000 \text{ K} \)). Times \( t \geq 0.1 \text{ ns} \) correspond to the \( \alpha \) relaxation, where \( C_q(t_w, t_w + t) \) decays from the plateau to zero. For the quench
from 5000 to 2500 K (see Fig. 4) this decay depends on $t_w$ for all $t_w < 8.83 \text{ ns}$. However, for $t_w \geq 8.83 \text{ ns}$ (the largest three $t_w$), $C_q(t_w, t_w + t)$ is independent of $t_w$ not only for intermediate times $t$ (plateau) but for all times (including the $\alpha$ relaxation). Thus, the system reaches equilibrium during the simulation run. For the quench from 3760 to 3000 K (see Fig. 6), $C_q(t_w, t_w + t)$ becomes independent of $t_w$ for $t_w \geq 1 \text{ ns}$, which means that the time at which equilibrium is reached is dependent on the temperature quench.

To estimate the time when the system reaches equilibrium for each $(T_i, T_f)$ combination, we next quantify the decay of $C_q(t_w, t_w + t)$. Instead of taking a vertical cut in $C_q(t_w, t_w + t)$ as we did for $F$, we now take a horizontal cut. We define the decay time $t_C(t_w)$ to be the time $t = t_C(t_w)$ for which $C_q(t_w, t_w + t_C(t_w)) = C_{out}$. We chose $C_{out} = 0.625/0.41/0.295/0.155/0.085/0.04$ for the Si particles and $C_{out} = 0.625/0.305/0.195/0.08/0.04/0.014$ for the O particles at the wave numbers $q = 1.7/2.7/3.4/4.6/5.5/6.6 \text{ Å}^{-1}$, respectively. The resulting decay times $t_C(t_w)$ as a function of waiting time $t_w$ are shown in Fig. 7(a) for O-atoms and in Fig. 7(b) for Si-atoms. Color (black or green/gray) indicates the initial temperature $T_i$ and symbol shape indicates the final temperature $T_f$.

We find that $t_C(t_w)$ is characterized by three different $t_w$ windows. (I) For waiting times $t_w \geq 0.3 \text{ ns}$, decay times are significantly lower for $T_f = 5000 \text{ K}$ (black lines and symbols) than for $T_i = 3760 \text{ K}$ (green/gray lines and symbols). The dependence of $t_C(t_w)$ on $t_w$ is strongly dependent on all varied parameters, i.e., $T_i, T_f, \text{ particle type, and } q$. For $T_f = 5000 \text{ K, } T_i = 2500 \text{ K, } 2750 \text{ K, and } q = 1.7 \text{ Å}^{-1}, 2.7 \text{ Å}^{-1}$ $t_C(t_w)$ follows roughly a power law with an exponent $\mu \approx 1.15$ with variations of the order of 0.07 dependent on $T_i, \text{ particle type, and } q$. (II) For intermediate waiting times, $t_C(t_w)$ also follows roughly a power law with a different exponent than in regime (I). We find for $T_i = 5000 \text{ K, } T_f = 2500 \text{ K, } 2750 \text{ K, and } q = 1.7 \text{ Å}^{-1}, 2.7 \text{ Å}^{-1}$ $\mu = 0.35$ with variations of the order of 0.08 depending on $T_i, \text{ particle type, and } q$. Best power law fits are for $T_i = 3760 \text{ K, } T_f = 2500 \text{ K with } \mu \text{ ranging from } 0.55/0.57 \text{ for } q = 1.7 \text{ Å}^{-1} \text{ to } 0.69/0.63 \text{ for } q = 6.6 \text{ Å}^{-1}$ and for Si/O atoms. Kob and Barrat find for the binary Lennard-Jones system also a power law for $t_C(t_w)$, however, with $\mu = 0.882$ [16]. Similar to Grigera et al. [50] we find that the transition from small waiting times (I) to intermediate waiting times (II) is accompanied by a change of the exponent $\mu$. (III) For very long waiting times $t_C(t_w)$ is independent of $t_w$ and $t_f$, i.e., equilibrium is reached. The waiting time $t_{23}$ for which the transition from regime (II) to regime (III) occurs is dependent on $T_i$: $t_{23} = 0.3 \text{ ns}$ for $T_i = 3250 \text{ K, } t_{23} = 1 \text{ ns}$ for $T_i = 3000 \text{ K, } t_{23} = 3 \text{ ns}$ for $T_i = 2750 \text{ K, and } t_{23} = 10 \text{ ns}$ for $T_i = 2500 \text{ K}$ [51].

Mean-field spin-glass models predict [8,9]

$$C_q(t_w, t_w + t) = C_{q \text{ ST}}(t) + C_{q \text{ AG}}\left(\ln(t_w + t)/\tau_{\text{fit}}\right),$$

according to which $C_q(t_w, t_w + t)$ can be separated into a short-time term $C_{q \text{ ST}}(t)$ that is independent of $t_w$ and an intermediate-time term that scales as $h(t_w + t)/h(t_w)$ where $h$ is a monotonously increasing function. It has been observed for different systems that the function $h(t)$ follows $h(t) \approx t^\gamma$. Thus, the so-called “simple aging” (see [16] and references therein) applies and, as a consequence, $C_q$ as a function of $(t/t_w)$ for different $t_w$ superimpose.

Müssel and Rieger [52] have proposed activated dynamics for $C_q(t_w, t_w + t)$,

$$C_q(t_w, t_w + t) = C_{q \text{ ST}}(t) + C_{q \text{ AG}}\left(\ln[(t_w + t)/\tau_{\text{fit}}]\right),$$

where the characteristic time scale $\tau_{\text{fit}}$ is a fit parameter. We find that neither $C_{q \text{ ST}}(t)$, nor $C_{q \text{ AG}}$, nor $C_{q \text{ AG}}\left(\ln[(t_w + t)/\tau_{\text{fit}}]\right)$ (for any choice of $\tau_{\text{fit}}$) superimpose for different $t_w$. Instead we find, similar to the results of Kob and Barrat [16] for a binary Lennard-Jones system, that time superposition holds, defined by
In Fig. 8, we show $C_q(t_i/t_{Cq}^0)$ for the same set of parameters as in Fig. 4. When all waiting times are included (see inset of Fig. 8) time superposition does not apply due to including too short waiting times. Wahlen and Rieger [26] have studied $C_q(t_w,t_w+t)$ for the same BKS-SiO$_2$ system, however for waiting times smaller than 50 ps. Their results are consistent with the inset of Fig. 8. For waiting times $t_w \geq 0.49$ ns (see Fig. 8), however, Eq. (6) is a good approximation. Please note that $C_q(t_i/t_{Cq}^0)$ follows time superposition for all waiting times $t_w \geq 0.49$ ns, i.e., not only for the time-range (II), but also for the time-range (III). That means for the $\alpha$-relaxation that the shape of the out-of-equilibrium curves is the same (within error bars) as the shape of the equilibrium curves. We find similar results for all other $(T_i,T_f)$ combinations, Si-particles, and all other $q$.

Next we test whether $C_q = C(q,t_w,t_w+t)$ scales as $C_q = C_q(z,t_w,t)$ where $z$ is a function of $t_w$ and $t$ only, i.e., independent of $q$. Following an approach of Kob and Barrat [17] we show in Fig. 9 a parametric plot for $C_q(t_w,t_w+t)$ as a function of $C_q(t_w,t_w+t)$ for $q=1.7$ Å$^{-1}$ and, $q'=2.7,3.4,4.6,5.5,6.6$ Å$^{-1}$ for O-atoms and the temperature quench from 5000 K to 2500 K. For sufficiently large $t_w$ we find, contrary to the results of Kob and Barrat for the Lennard-Jones system, that for SiO$_2$ the parametric curves superimpose and thus that $C(q,t_w,t_w+t) = C(q,z(t_w,t))$ for $t_w \geq 0.49$ ns. This includes, within error bars, also the equilibrated curves for $t_w \geq 10$ ns. We find similar results for all other $(T_i,T_f)$ combinations, Si-particles, and all other $q$.

C. Mean square displacement

In the previous section, we have focused on the analysis of $C_q(t_w,t_w+t)$ and identified different time windows. In this section, we consider the mean-square displacement $\Delta r^2(t_w,t_w+t)$ as defined in Eq. (7) for the temperature quench from 5000 K to 2500 K and for O-atoms. Waiting times and corresponding line styles are the same as in Fig. 4.

Figure 10 shows $\Delta r^2(t_w,t_w+t)$ for the temperature quench from 5000 K to 2500 K and for O-atoms. As in Fig. 4, for times $t \approx 5 \times 10^{-3}$ ns and zero waiting time, the mean square displacement $\Delta r^2(t_w=0,t)$ is well approximated by $\Delta r^2$ of the high temperature $T_i=5000$ K from which the system has been quenched (see dashed line in Fig. 10) and thus independent of $T_f$. For times $t \approx 10^{-2}$ ns, $\Delta r^2(t_w,t_w+t)$ is oscillatory due to the small system size [31], while for times $t \approx 10^{-3}$ ns and waiting times $t_w \approx 0.33$ ns, we find that $\Delta r^2$ forms a plateau, which is independent of $t_w$. As for $C_q$, we find that the plateau is the more horizontal the smaller $T_f$ and the plateau height depends on the particle type but is independent of $T_i$.

For waiting times $t_w \approx 0.33$ ns and times $t \approx 0.1$ ns, the mean-square displacement leaves the plateau and increases.
The critical MCT temperature $T_c$, using the BKS potential to model the interactions between silicon and oxygen atoms. After an instantaneous quench from $T_i>T_c$ to a temperature $T_i\leq T_c$, the dynamics toward equilibrium was studied as a function of waiting time $t_w$. Note that the temperatures $T_i$ were chosen such that equilibrium was reached on the time span of the simulations (of the order of 30 ns). The central quantities considered in this work are the incoherent intermediate scattering function $C_q(t_w,t_w+i)$ and the mean square displacement $\Delta r^2(t_w,t_w+i)$. These functions depend on the time origin at $t_w$ as long as $t_w$ is smaller than the typical relaxation time, $\tau_{eq}$, that is required to equilibrate the system.

We find that the decay of $C_q(t_w,t_w+i)$ (and similarly the rise of $\Delta r^2(t_w,t_w+i)$) exhibit qualitative changes from short to long waiting times. At short waiting times, relaxation processes are dominant that correspond to the early $\beta$ relaxation regime at the target temperature $T_i$. In this $t_w$ regime, no well-defined plateau is found in $C_q(t_w,t_w+i)$ (see Fig. 4). Instead, this function first decreases rapidly, followed by a strongly stretched exponential decay to zero. At long waiting times, the $\beta$ relaxation seems to be very similar to that at equilibrium. The Debye-Waller factor (i.e., the height of the plateau in $C_q(t_w,t_w+i)$) has reached its equilibrium value, although the decay of $C_q(t_w,t_w+i)$ from the plateau to zero is faster than that at equilibrium. However, the shape of curves describing the long-time decay of $C_q(t_w,t_w+i)$ is the same as that at equilibrium. Thus, $C_q$ follows a simple time superposition for long waiting times, different e.g., from the “activated dynamics scaling” proposed by Wahlen and Rieger for BKS silica.

Our results show that the aging dynamics of BKS silica is very similar to that of the KALJ mixture. For both silica and the KALJ mixture three $t_w$-regimes can be identified and $C_q$ follows time superposition for sufficiently large $t_w$. The only difference between these two systems is that $C_q$ scales as $C(q,z,t_{eq})$ for SiO$_2$ but less well for the KALJ mixture. So slightly below its critical temperature $T_c$ of MCT, the strong glass-former silica does not seem to be very different from typical fragile systems, although one has already reached the low temperature Arrhenius regime (note that activation energies for the self-diffusion, viscosity etc. are of the order of 5 eV, similar to the corresponding activation energies close to the glass transition temperature $T_g\approx 1450$ K, as measured in various experiments). However, the dynamics could be very different at very low temperatures (close to $T_g$) where the long-time aging regime is not accessible by computer simulations. Thus, more experimental work on the aging dynamics of silica around $T_g$ would be very desirable. We also leave for future work to test whether also for other systems three $t_w$ regimes are identified and whether the equilibrium curve is included in the time superposition of $C_q$ at intermediate and large $t_w$.

APPENDIX: VELOCITY VERLET NOSÉ HOOVER

The Nosé Hoover equations of motion are for particles $i=1,\ldots,N$ at position $\mathbf{r}_i$ with momentum $\mathbf{p}_i$

$$\dot{\mathbf{r}}_i = \frac{\mathbf{p}_i}{m_i},$$  \hspace{1cm} (A1)

$$\dot{\mathbf{p}}_i = \mathbf{F}_i - \zeta \mathbf{p}_i,$$  \hspace{1cm} (A2)

$$\dot{\zeta} = \frac{1}{Q} \left( \sum_{i=1}^{N} \frac{p_i^2}{m_i} - XkT \right),$$  \hspace{1cm} (A3)

and thus

$$\dot{\mathbf{r}}_i = \frac{\mathbf{F}_i}{m_i} - \zeta \dot{\mathbf{r}}_i,$$  \hspace{1cm} (A4)

$$\frac{d^2 \ln s}{dr^2} = \dot{\zeta} = \frac{1}{Q} \left( \sum_{i=1}^{N} m_i \dot{r}_i^2 - XkT \right),$$  \hspace{1cm} (A5)

where $X=3N$. We integrated with the generalized velocity Verlet form of Fox and Andersen [53]

$$\mathbf{r}_i(t+\Delta t) = \mathbf{r}_i(t) + \Delta \mathbf{r}_i(t) + \frac{(\Delta t)^2}{2} \left[ \frac{\mathbf{F}_i(t)}{m_i} - \zeta(t) \dot{\mathbf{r}}_i(t) \right],$$  \hspace{1cm} (A6)

To ensure that $\sum_{i=1}^{N} \frac{p_i^2}{2m_i} + U(\{\mathbf{r}_i\}) + \frac{Q}{2} \zeta^2 + XkT \ln s$ is conserved (see [48]) we chose $Q=50000$ $\text{Å}^2$ u.
[43] The erfc was approximated with a polynomial of fifth order [54].
[45] Please note that we chose all parameters as described in [44] with the only exception of $a_{2,O} = 895.11679$ eV/Å (instead of $a_{2,O} = 90.38499$ eV/Å).
[49] Both the duration of the NVT-simulation run, as well as the Nosé-Hoover parameter $Q$ were chosen carefully such that $Y$ and $E_{\text{tot}}$ were constant during the NVT and NVE runs, respectively.
[51] These estimates of $t_{23}$ are in good agreement with the results of Scheidler et al. [39] who determined the relaxation time via the specific heat and who found good agreement with experimental data.
